Abstract

Taiwan deregulated its wireless telecommunication services in 1997. Fierce competition followed, and churn management becomes a major focus of mobile operators to retain subscribers via satisfying their needs under resource constraints. One of the challenges is churner prediction. Through empirical evaluation, this study compares various data mining techniques that can assign a 'propensity-to-churn' score periodically to each subscriber of a mobile operator. The results indicate that both decision tree and neural network techniques can deliver accurate churn prediction models by using customer demographics, billing information, contract/service status, call detail records, and service change log.

Keywords: Churn management; Wireless telecommunication; Data mining; Decision tree; Neural network

1. Introduction

Taiwan opened its wireless telecommunication services market in 1997, with licenses granted to six mobile operators. Competition has been fierce from this point. For any acquisition activity, mobile operators need to have significant network investment to provide ubiquitous access and quality communications. The market was saturated within 5 years, and mergers and acquisitions reduced the number of mobile operators from six to four by the end of 2003.

When the market is saturated, the pool of ‘available customers’ is limited and an operator has to shift from its acquisition strategy to retention because the cost of acquisition is typically five times higher than retention. As Matterson (2001) noted, ‘For many telecom executives, figuring out how to deal with Churn is turning out to be the key to very survival of their organizations’.

Based on marketing research (Berson, Smith, & Thearling, 2000), the average churn of a wireless operator is about 2% per month. That is, a carrier lost about a quarter of its customer base each year. Furthermore, Fig. 1 suggests that Asian telecom providers face a more challenging customer churn than those in other parts of the world.

From a business intelligence perspective, churn management process under the customer relationship management (CRM) framework consists of two major analytical modeling efforts: predicting those who are about to churn and assessing the most effective way that an operator can react (including ‘do nothing’) in terms of retention. This research focuses on the former. It intends to illustrate how to apply IT technology to facilitate telecom churn management. Specifically, this research uses data mining techniques to find a best model of predictive churn from data warehouse to prevent the customers turnover, further to enhance the competitive edge.

The remainder of this paper is organized as follows. Section 2 defines some basic concepts (and rationale) that we use in the research, Section 3 describes our research methodology, and Section 4 presents the findings. Section 5 concludes this paper.

2. Basic concept

2.1. Churn management

Berson et al. (2000) noted that ‘customer churn’ is a term used in the wireless telecom service industry to denote the customer movement from one provider to another, and ‘churn management’ is a term that describes an operator’s process to retain profitable customers. Similarly, Kentrias (2001) thought that the term churn management in the telecom services industry is used to describe the procedure of securing the most important customers for a company. In essence, proper customer management presumes an ability to forecast the
customer decision to move from one service provider to another, a measurement of ‘customer profitability’, and a set of strategic and tactic retention measures to reduce the movement (Lariviere & Van den Poel, 2004).

In practice, an operator can segment its customers by ‘profitability’ and focus retention management only on those profitable segments, or score the entire customer base with ‘propensity to churn’ and prioritize the retention effort based on profitability and churn propensity. However, the telecom services industry is yet to standardize a set of ‘profitability’ measurements (e.g. current versus life-time, business unit versus corporate, account versus customer, ‘loyalty’ versus ‘profitability’, etc.). This research focuses on churn prediction, and assumes low correlation between ‘profitability’ and ‘propensity to churn’ to simplify the modeling framework.

2.2. Data mining

Thearling (1999) proposed that data mining is ‘the extraction of hidden predictive information from large databases’, a cutting-edge technology with great potential to help companies dig out the most important trends in their huge database. Emerging data mining tools can answer business questions that have been traditionally too time-consuming to solve. Lejeune (2001) addressed that data mining techniques allow the transformation of raw data into business knowledge. The SAS Institute (2000) defines data mining as ‘the process of selecting, exploring and modeling large amount of data to uncover previously unknown data patterns for business advantage’. Consequently, we would say that data mining is applying data analysis and discovery algorithms to detect patterns over data for prediction and description.

With sufficient database size and quality, data mining technology can provide business intelligence to generate new opportunities (Lau, Wong, Hui, & Pun, 2003; Su, Hsu, & Tsai, 2002; Zhang, Hu, Patuwo, & Indro, 1999; Langley & Simon, 1995; Bortiz & Kennedy, 1995; Fletcher & Goss, 1993; Salchenberger, Cinar, & Lash, 1992; Tam & Kiang, 1992). In CRM, data mining techniques most commonly used include clustering, associations, rule induction, genetic algorithm, decision tree, and neural network.

2.3. Data mining application

Table 1 below summarizes some data mining functionalities, techniques, and applications in the CRM domain.

</table>
This research selected decision tree, neural network and K-means cluster as data mining techniques to build predictive models or segment customers.

Note that in addition to conducting empirical research, we can use the same IT infrastructure to collect, analyze, detect, and eliminate major customer churn factors. This ‘closed loop’ infrastructure is imperative to business management as we manage churn to sustain our relationship with customers.

### 3.2. Prediction model creation process

**Fig. 3** shows our process of creating a predictive model.

#### 3.2.1. Define scope

In this study, we focus on the post-paid subscribers who pay a monthly fee and were activated for at least 3 months prior to July 1, 2001. A churner is defined as a subscriber who is voluntary to
leave; non-churner is the subscriber who is still using this operator’s service. Moreover, we used the latest 6 months transactions of each subscriber to predict customer’s churn probability of the following month. The transaction data include billing data, call detail records (CDR), customer care, etc.

### 3.2.2. Exploratory data analysis (EDA)

The purpose of EDA is to explore from the customer database those possible variables that can characterize or differentiate the customer behavior. For the variables extraction, we interviewed telecom experts, such as telecom business consultants, marketing analysts, customers, and sales of mobile provider to identify churn causes or symptoms prior to customer churn, such as ‘contract expired’, ‘low usage’, or ‘query about terminating the contract’.

### 3.2.3. Data preprocessing, variable analysis and selection, and data extraction

Based on the results of interviews with experts, we extract some possible variables from the customer database as an analytical base of EDA to determine which variables are useful to differentiate between churners and non-churners.

For each of the causes/symptoms gained from interviews, we start to determine if we can observe similar customer behavior from the database. For example, to the symptom ‘contract expired’ we can define a variable ‘number of days behavior from the database. For example, to the symptom ‘contract expired’, we start to determine if we can observe similar customer behavior. For the variables extraction, we interviewed telecom experts, such as telecom business consultants, marketing analysts, customers, and sales of mobile provider to identify churn causes or symptoms prior to customer churn, such as ‘contract expired’, ‘low usage’, or ‘query about terminating the contract’.

### 3.2.4. Machine learning (model creation)

We took two approaches to assess how models built by decision tree (C5.0) and back propagation neural network (BPN) techniques perform.

In Approach 1, we used K-means clustering methods to segment the customers into five clusters according to their billing amount (to approximate ‘customer value’), tenure months (to approximate ‘customer loyalty’), and payment behaviors (to approximate ‘customer credit risks’). Then we create a decision tree model in each cluster (see Approach 1 in Fig. 3). This is to assess if the churn behaviors are different in different ‘value-loyalty’ segments.

In Approach 2 (see Approach 2 in Fig. 3), we used neural network to segment customers, followed by decision tree modeling. This is a technology assessment to test if BPN can improve DT prediction accuracy.

### 3.3. Model performance evaluation

In actual practice, it is necessary to know how accurate a model predicts and how long before the model requires maintenance.

To assess the model performance, we use LIFT and hit ratio. The following chart illustrates their definitions, where $A$ is the number of subscribers predicted to churn in the predictive time window who actually churned, $B$ is the number of subscribers predicted to churn but did not.

Hit ratio is defined as $A/(A + B)$, instead of $(A + D)/(A + B + C + D)$. This is a model effectiveness measurement in predicting churners instead of predicting all customer behavior in the predictive window.

To assess LIFT, we have to rank order all customers by their churn score, and define hit ratio ($X\%$) as the hit ratio of the ‘$X\%$ Customers with top churn score’. LIFT ($X\%$) (is this $X\%$ the same as the other?) is then defined as the ratio of hit ratio ($X\%$) to the overall monthly churn rate. For example, if the overall monthly churn rate = 2%, $X = 5$, and hit ratio (5%) = 20%, then LIFT (5%) = $20/2\% = 10$. LIFT is a measure of productivity for modeling: with random sampling of the entire customer base you would yield 2% churners, focusing instead on the 5% Top-Churn-Score customers you would yield 20% churners. (Note that in this case, the top 5% contains 50% of the total churners.)

To assess model robustness, we monitor each month’s model hit ratio and LIFT for an extended period of time to detect degradation.

### 4. Empirical finding

#### 4.1. Data source

A wireless telecom company in Taiwan provides their customer related data. To protect customer privacy, the data source includes data of about 160,000 subscribers, including 14,000 churners, from July 2001 to June 2002, randomly selected based on their telephone numbers.

#### 4.2. Exploring data analysis results

We developed possible variables from other research and interviews with telecom experts. We then analyzed these variables with z-test from four dimensions and listed significant variables of churn below, based on our analysis database.

- **Customer demography**
  - Age: analysis shows that the customers between 45 and 48 have a higher propensity to churn than population’s churn rate.
Tenure: customers with 25 – 30 months tenure have a high propensity to churn. A possible cause is that most subscription plans have a 2-year contract period.

Gender: churn probability for corporate accounts is higher than others. A possible cause is that when employees quit, they lose corporate subsidy in mobile services.

Bill and payment analysis
- Monthly fee: the churn probability is higher for customers with a monthly fee less than $100 NT or between $520 and $550.
- Billing amount: the churn probability tends to be higher for customers whose average billing amount over 6 months is less than or equal to $190 NT.
- Count of overdue payment: the churn probability is higher for customers with less than four counts of overdue payments in the past 6 months. In Taiwan, if the payment is 2 months overdue, the mobile operator will most likely suspend the mobile service until fully paid. This may cause customer dissatisfaction and churn.

Call detail records analysis
- In-net call duration: customers who don’t often make phone calls to others in the same operator’s mobile network are more likely to churn. In-net unit price is relatively lower than that of other call types. Price-sensitive subscribers may leave for the mobile operator his/her friends use.
- Call type: customers who often make PSTN or IDD calls are more likely to churn than those who make more mobile calls.

Customer care/service analysis
- MSISDN change count: customers who have changed their phone number or made two or more changes in account information are more likely to churn.
- Count of bar and suspend: customers who have ever been barred or suspended are more likely to churn. In general, a subscriber will be barred or suspended by the mobile operators due to overdue payments.

Table 2 summarizes variables significant to differentiate between churners and non-churners from EDA. We use those variables for machine learning.

4.3. Customer segmentation

To segment customers by loyalty, contribution, and usage, we selected bill amount, tenure, MOU (outbound call usage), MTU (inbound call usage), and payment rate as variables and used K-Means to model the customers into five clusters. To generate roughly the same number of subscribers in each of the five clusters, we divided the customers equally into three segments high, medium, and low for each variable.

Table 3 and Fig. 4 summarize the clustering results. Note that each cluster has its unique characteristics:

4.4. Supervise machine learning

4.4.1. Decision tree

In this research we use the decision tree technique to create many models under different scenarios. One of the scenarios is to create a decision tree model for all the customers. Another one is to create separate decision tree models in each of the customer segments.

4.4.1.1. Decision tree modeling without customer segmentation.

From EDA we select about 40 variables for C5.0 decision tree modeling. We use many different training sets to create models, and use the same data set for model validation and performance tests. We compare model performance based on LIFT (10%), that is, the LIFT of the 10% subscribers with the top churn scores.

The churn rate of the whole population is only 0.71%. We over-sample the churners to get a higher churn rate training set for machine learning. Table 4 summarizes the results of six different sampling strategies for machine learning. For example, the training set of the model S1-1M-RS-30K contains 30 K randomly sampled subscribers while that of the model S1-1M-P3 contains 36.7 K subscribers with a 3% over-sampling of churners.

Table 4 shows that model S1-1M-P5 has the highest LIFT (10%), about 10. It means that the performance of using a 1-month analytical window to predict the possible churners of next month will be better than others.

4.4.1.2. Decision tree modeling with customer segmentation.

Since all customers have been assigned to a cluster identity, we separate the training sets into five sub-sets for decision tree
modeling by the cluster identity. Then we used the same validation sets to evaluate all models. Table 5 shows the performance of each clusters’ decision tree model.

4.4.2. Neural network (back propagation network, BPN)

Based on other research results (e.g. Cybenko, 1998; Zhan, Patuwo, & Hu, 1998), we know that using one-layer hidden layer and optimal network design might provide a more accurate model from neural network. In this study, we use 1-1-1 (input-hidden-output) as a training model type. This training type includes 43 inputs and only one output. Since public information is not available on key modeling parameters such as the learning rate or number of neurons in the hidden layer, we try many different combinations. Table 6 shows the results, in which model N18-R6, for example, uses 18 neurons in the hidden layer with 0.6 learning rate.

To minimize other variances, we use the same training set for BPN as for decision tree. Table 6 shows that N21-R6 achieves the best performance from R-square and MSE measurements.

4.5. Model performance stability

4.5.1. Overall performance trend

We use the data from the telecom operator to ‘track’ model performance over a period of time. Fig. 5 shows the trend of performance in terms of hit rate and capture rate:

- Fig. 5 shows that all the models demonstrate stable accuracy in the first 6 months. However, significant degradation occurs in the month of February 2002, regardless of modeling techniques. The Chinese New Year is in February 2002 and it is possible that consumers behave differently during this period.
- In the first 6 months, NN outperforms DT, and DT without segmentation slightly outperforms DT with segmentation.

In general, the performance of building a predictive model on individual segments is more accurate than the one built on the entire customer population. Thus, a decision tree model without segmentation should outperform a decision tree model with segmentation. Our experiment shows otherwise. Furthermore, we are concerned about the significant performance gap after the first month between the NN and DT techniques.

4.5.2. Test modeling technique differences

We use T-test to compare modeling techniques under different modeling parameters. The hypotheses are:

- H01: hit ratio of the decision tree model without segmentation is not different from that with segmentation. (DTH-DTSH)
- H02: capture rate of the decision tree model without segmentation is not different from that with segmentation. (DTC-DTSC)
- H03: hit ratio of the neural network model is not different from the decision tree model without segmentation. (NNH-DTH)
- H04: capture rate of the neural network model is not different from the decision tree model without segmentation. (NNC-DTC)
- H05: hit ratio of the neural network model is not different from the decision tree model with segmentation. (NNH-DTSH)
- H06: capture rate of the neural network model is not different from the decision tree model with segmentation. (NNC-DTSC)

Table 7 lists T-test results:

- The performance of the decision tree model without segmentation is better than that with segmentation.
The performance of BPN is better than the decision tree model without segmentation on both hit ratio and capture rate.

4.5.3. Sample size impact

One theory is that our results are biased because of limited churn samples in the analysis base: the mobile service provider only budgeted this study at the population of about 160,000 customers, and the associated monthly churn rate was only 0.71%. The data size was not sufficient to build a good predictive model by each customer segment because we could not explore real significant information from a few churners in each customer segment. For example, Table 3 shows that C3 contains about 17% of the customer population with a 0.3% churn rate. Thus, there are only $160,000 \times 0.3\% \approx 80$ churners in C3.

4.5.4. Robust models

In order to validate the model’s accuracy, we randomly selected 50,000 subscribers to evaluate the model’s performance. Fig. 6 shows the results: models built are more robust and performance disparity between NN and DT models in the first 6 months disappeared.

Fig. 7 compares the LIFT of all models: both NN and DT techniques generate models with a hit rate of 98% from the top 10% of predicted churners in the list. That is, LIFT (10%) is about 10.

4.5.5. Performance comparison with prior studies

Berson et al. (2000) used customer demographics, contractual data, and customers’ service data as predictors to generate models with a hit rate of about 40% from the top 10% of predicted churners in the list. That is, LIFT (10%) is about 4. Wei (Wei & Chiu, 2002) used customer call detail records as a predictor and generated models with a hit rate of less than 50% from the top 10% of predicted churners in the list. That is, LIFT (10%) is less than 5. Our LIFT (10%) is about 10. Although the customer bases are different and there are other modeling parameters to consider, the LIFT achieved by all proposed techniques in this study demonstrates a significant improvement from those in early studies.

5. Conclusions and future research

Churn prediction and management is critical in liberalized mobile telecom markets. In order to be competitive in this market, mobile service providers have to be able to predict possible churners and take proactive actions to retain valuable customers.

In this research, we proposed different techniques to build predictive models for telecom churn prediction. We included customer service and customer complaint log for modeling, as suggestions from prior research of Wei and Chiu (2002). We examined the impact of inadequate data on model building. Our empirical evaluation shows that data mining techniques...
can effectively assist telecom service providers to make more accurate churn prediction. However, the effective churn prediction model only supports companies to know which customers are about to leave. Successful churn management must also include effective retention actions. Mobile service providers need to develop attractive retention programs to satisfy those customers. Furthermore, integrating churn score with customer segment and applying customer value also helps mobile service providers to design the right strategies to retain valuable customers.

Data mining techniques can be applied in many CRM fields, such as credit card fraud detection, credit score, affinity between churners and retention programs, response modeling, and others.
